A B S T R A C T

Corporate exposure management in response to the changes in crude oil prices would demand predictive models that can adjust themselves to macroeconomic shocks of the moment. In the past, risk managers used the autoregressive models such as the GARCH which are based on the assumption that market volatility remains at a predictable, linear rate. Nevertheless, this empirical research shows through a Chow Test ($ F = 12.84, p < 0.01) that the world oil market suffered a critical structural break-in the year 2020. Volatility dynamics changed their regime forever as driven by kinetic geopolitical conflicts and algorithmic news trading had switched to exogenous, regime-driven shock. In order to take this new market microstructure, we present the Oil Volatility Intelligence Platform (OVIP), a non-linear Dual-Model Machine Learning architecture. The service deciphers sequence-encoded narrative sentiment of 45,000 financial writings with a FinBERT Large Language Model, and links these indicators with Markov-Switching regime likelihoods. In order to remove the extremely toxic multicollinearity (Max VIF = 27.24) that exists between time-series momentum features, we use Principal Component Analysis (PCA) before they are consumed by a Random Forest algorithm. The bifurcated framework is tested strictly out-of-sample between 2021 and 2025 and has a 69.1% Directional Accuracy and captures the precise size of the volatility spikes with the R-squared of 20.10. By converting these econometric measurements into corporate utility, a simulation based on dynamic portfolio hedging illustrates that in comparison to naive baseline compensation strategies, there is a cumulative economic alpha of + 2.46%. This is an extremely robust, production-ready decision support system in contemporary commodity markets.

1. Introduction

West Texas Intermediate (WTI) crude oil into the global market supplies two hundred billion to a trillion financial exposure, and has become the central nervous system of the commercial supply chains, sovereign wealth funds, and transportation conglomerates. To the organizations that are crippled by the enormous amount of jet fuel or diesel costs, the volatility of this commodity cannot be accurately predicted; it is a matter of survival to dynamic portfolio hedging and corporate risk management.

The overall consensus method of modeling this risk over the past 40 years has been based on the Generalized Autoregressive Conditional Heteroskedasticity (GARCH) family of equations [5], [11]. These classical models are founded on the basis idea of persistence the idea that future market variance is a decaysing lineal reflection of the past variance. Linear autoregression is mathematically beautiful at times of macroeconomic peace, but it has a fatal forecasting weakness. It is blind by its very nature to exogenous shocks.

The early 2020s fundamentally rewrote the mechanics of commodity pricing. The convergence of the COVID-19 demand collapse, the 2022 kinetic conflicts in Eastern Europe, and the weaponization of global supply quotas shattered the traditional persistence assumption. Volatility became highly discontinuous. We hypothesize—and mathematically confirm in this study—that the crude oil market suffered a permanent structural break in the year 2020. Price movements are no longer dictated primarily by physical inventory reports, but rather by the rapid propagation of global narratives and algorithmic news trading. When a predictive financial model ignores textual sentiment and geopolitical rhetoric, it inevitably suffers catastrophic out-of-sample failure.

The beginning of 2020 redefined the principles of pricing commodities. The traditional assumption of persistence was torn apart due to the convergence of the demand collapse in 2019 because of the COVID-19 pandemic, the 2022 kinetic conflicts in Eastern Europe, and the weaponization of the world supply quotas. Volatility was extremely discontinuous. We make a hypothesis--which we prove mathematically in this work--that the crude oil market experienced a structural breach in the year 2020 that will be permanent. It is not physical inventory reports that now set the price movements, but the speed with which global stories and algorithmic news trading spread. Once a predictive financial model predicts on the principle that textual sentiment and geopolitical rhetoric do not matter, it invariably fails disastrously out of sample.

To address this forecasting shortcoming, the current paper offers the Oil Volatility Intelligence Platform (OVIP). We construct a Dual-Model Machine Learning that is regime switching specific. Going beyond univariate price analysis, OVIP measures Narrative Economics [17]. The system uses FinBERT a Bidirectional Encoder Representations from Transformers architecture fine-tuned to financial lexicons [2] to retrieve continuous sentiment probabilities on tens of thousands of articles on energy across the world. This interaction of these text-based signals with Markov-Switching regime probabilities [12] and with Geopolitical Risk (GPR) indices [7] forms a fine-scale, 11-Pillar predictive engine.

Using machine learning on collinear macroeconomic indicators regularly causes worst-case multicollinearity, annihilating the matrix computations of usual baseline algorithms. As a way to avoid this mathematical bottleneck, our algorithm applies Principal Component Analysis (PCA) in order to orthogonalize very strongly correlated momentum features and send them into a non-parametric Random Forest Regressor [6]. Since tree-based bagging designs use recursive spatial partitions instead of matrix inversion, the model is able to effectively circumvent Variance Inflation Factor (VIF) constraints without being susceptible to the noise-chasing nature of gradient boosting models that are fitted to financial data.

This study makes two main contributions. To begin with, we offer strong empirical evidence that our bifurcated model achieves significantly higher performance in post-2020 out-of-sample testing, which is unseen and in the strictest sense, as compared to traditional econometrics. Second, We convert abstract information on data science to concrete decision support by converting our data scientific out performance into measurable corporate hedging alpha.

2. Literature review and research gap

2.1 The Evolution and Limitations of Volatility Persistence

The early asset pricing models, including the Black-Scholes-Merton model [4], assumed that volatility is constant. Empirical studies of financial time-series quickly confirmed this assumption however, showing that large price changes are often preceded by large changes and small changes by small changes- a phenomenon known as volatility clustering [15]. To describe this conditional heteroskedasticity mathematically, Engle [11] proposed the Autoregressive Conditional Heteroskedasticity (ARCH) model, which was later extended by Bollerslev [5] to the GARCH model. Standard GARCH(1,1) model specifies conditional variance h t as a linear expression of the previous squared residuals.

$$h_t = \omega + \alpha \varepsilon_{t-1}^{2} + \beta h_{t-1}$$

Asymmetric shocks GARCH variants (with EGARCH by Nelson [16] being one) used to be the industry standard over several decades. The weakness of the GARCH family, however, lies in the fact that it depends on the persistence parameter, which is the parameter that assumes the presence of the persistence 2. Deterministic structural changes in the unconditional variance of a time-series can badly upward-bias estimating GARCH persistence as was shown by Lamoureux and Lastrapes [13]. In case of an exogenous geopolitical shock, the market has a structural breakage. Linear autoregressive models are unable to adjust themselves to these new unconditional levels of persistence.

2.2 Regime-Switching Econometrics in Commodity Markets

In an attempt to stabilise the lapses that occurred in linear persistence in the face of structural breaks the literature migrated towards models that could be flexed to dynamic states. Hamilton [12] was the first to introduce the Markov-Switching Dynamic Regression model, in which the data-generating process may vary between unobserved, discrete states or in the regimes.

he Markov-switching model is the one that supposes that there is an unobservable state variables $s_t \in \{1, 2, \ldots, K$ A first-order Markov chain that is ruled by the transition matrix P leads to the process of the state evolution. The transition matrix in the case of two states is represented by,

$$P = \begin{bmatrix} p_{11} & p_{12} \\ p_{21} & p_{22} \end{bmatrix}, \text{where } p_{ij} = \Pr(s_t = j \mid s_{t-1} = \mathrm{i}),$$

While Markov-switching models can successfully classify the current state of the market, they are inherently univariate. As a result, they excel at identifying a crisis once it has begun but lack the exogenous information necessary to anticipate crises driven by external geopolitical narratives.

2.3 Exogenous Shocks: Policy Uncertainty vs. Geopolitical Risk.

Forecasting commodity volatility requires the addition of external macroeconomic variables. One well-known measure of the literature is the Economic Policy Uncertainty (EPU) index, as proposed by Baker et al. [3] to measure text-based media reporting on domestic fiscal and monetary policy debates.

Nonetheless, West Texas Intermediate (WTI) crude oil is a fungible commodity throughout the world. The arguments of Antonakakis et al. [1] are that crude oil prices are highly elastic to kinetic and cross-border shocks compared to local economic policy arguments. In turn, the preference of modern studies is the Geopolitical Risk (GPR) index created by Caldara and Iacoviello [7]. The GPR index base pairs thousands of newspapers around the world in an algorithmic process by counting words describing war, terrorism, and international tensions.

2.4 Narrative Economics and Transformer-Based NLP

The conceptualization of the viral migration of popular narratives as determinant of macroeconomic shifts was concretized by Shiller [17], who argued that the spread of popular story-telling can directly determine the macroeconomic shifts. The early quantitative finance used "Bag-of-Words" Natural Language Processing (NLP) to measure these narratives, based on specialized financial lexicons, like the Loughran and McDonald [14] financial dictionary.

Context blindness by a dictionary-based method is inherent. Context-aware NLP was transformed with the introduction of the Transformer architecture by Vaswani et al. [18] and the further creation of Bidirectional Encoder Representations from Transformers (BERT) by Devlin et al. [9]. In this paper, the author will use FinBERT [2], an LLM that has been fine-tuned on 10-K filings of corporations and Reuters financial news specifically. The bidirectional sequence framing of FinBERT provides it with the understanding of the highly-specific, counter-intuitive jargon of financial markets.

2.5 Machine Learning and the Multicollinearity Problem

The ordinance of Ordinary Least Squares (OLS) regression to Machine Learning (ML) in quantitative finance can be attributed to non-linear interactions, which are advised by ML. Nonetheless, there is an improvement of algorithms such as Extreme Gradient Boosting (XGBoost) that generate decision trees sequentially, and each decision tree tries to address the precise error in the residual of the last decision tree. It leads to XGBoost becoming a noise-chaser in fundamentally noisy situations, such as oil markets. The algorithm used in this study is the Random Forest (RF) algorithm as suggested by Breiman [6].

Being a bootstrap aggregating (bagging) ensemble, RF builds hundreds of independent decision trees on random selections of the data and averages the results, which automatically tends to smooth out stochastic noise. Moreover, RF achieves recursive feature partitioning, and it is mathematically immune to high Variance Inflation Factors (VIF) owed to highly correlated momentum predictors.

2.6 Research Hypotheses

Based on the gaps found in the classical linear persistence models, the structural realities of the contemporary macroeconomic system, and the newer discipline of Narrative Economics, the given research formalizes the following research hypotheses subject to test::

- **H1: Drivers of oil volatility experienced statistically significant structural breaks around 2020:** The objective of the hypothesis is to be tested with the assistance of the formal Chow Test on structural stability (Test 9), which mathematically determines phase shifts in the market-generating process of data.
- **H2: Regime-switching ML out-of-sample accuracy is better than persistence-based benchmarks:** This is measured by calculating the Out-of-Sample R 2 (Test 1) and the Clark-West Test of Equal Predictive Accuracy (Test 4) of the Dual-Model Machine Learning architecture against the pure GARCH(1,1) baseline.
- **H3: FinBERT sentiment gives incremental predictive value over traditional variables:** This is formally tested with Out-of-Sample Permutation Feature Importance (Test 13) where the precise changes in the model accuracy are computed when the FinBERT sequence-encoded NewsShock is randomly scrambled.
- **H4: Model performance is regime-systematically different.:** The hypothesis is discussed by using Hamilton Markov-Switching dynamic regression and then engineering interaction terms (e.g., LStateSSafe), which trains the algorithm conditional logic on bottom-up latent state Calm versus Crisis.

3. Data Architecture and Exploratory Data Analysis (EDA)

Oil Volatility Intelligence Platform (OVIP) is built on a very detailed multi-modal data structure. We constructed a dataset that generalized the non-linear realities of the modern commodity market, deeming between endogenous market measures and exogenous unstructured text and geopolitical texts.

3.1 Data Acquisition and Feature Taxonomy

All data collected is covered in a period of 25 years, starting on January 1, 2000, to December 31, 2025. This time frame was deliberately chosen to trace several macroeconomic climates, such as the Global Financial Crisis of 2008, the 2014 shale oil supply off, the 2020 demand destruction after the COVID-19 pandemic, and the 2022 Eastern European wars. In order to stop the bias of look-ahead, the data is defined as purely separate into an In-Sample Training Period (2000-2020) and an Out-of-Sample Testing Period (2021-2025). The data consumed is divided into three different taxonomic pillars such as Financial Market Data, Macro-Geopolitical Indices and Unstructured Textual Corpora.

3.1.1 Financial Market Data (Endogenous Variables)

- **West Texas Intermediate (WTI) Crude Oil Futures:** The data were obtained at the Chicago Mercantile Exchange (CME NYMEX) and we copied the prices of the active-month WTI contract in terms of daily continuous closed prices. Importance: This is the base ground truth of the study. Daily prices are transformed into continuous compounding logarithmic returns -3,4,5,34,5,34.6,7,8$r[i,t] = ln(P [i,t)/P [i-1,t]). The main target variable (that is, Realized Volatility (RVt)) is then obtained, which is the standard deviation of log-returns (annualized) of daily returns, over a 30-day rolling window of operation.
- **CBOE Crude Oil Volatility Index (OVX):** We have taken historical data that consists of daily values of the OVX that is the expectation of oil volatility in 30 days implicitly priced into the United States Oil Fund (USO) options. The OVX is a significant exogenous financial control. We can determine the precise premium given to fear and uncertainty by comparing the predictions of our model of realized volatility with the implied volatility in the market (OVX).

3.1.2 Macroeconomic and Geopolitical Indices (Exogenous Shocks)

- **The Geopolitical Risk (GPR):** This index was developed by Caldara and Iacoviello [7], and algorithmically sums how often terms of war, terrorism, and international tensions appear in 10 major newspapers in the world. More importantly, we have taken out of it the segregated sub-indices GPR-Threats (anticipatory rhetoric) and GPR-Acts (realized kinetic conflict). Significance: WTI is a commodity that is fungible globally, whereby it is severely susceptible to cross-supplier chain shocks. The GPR index enables the machine learning model to measure the intensity of international friction mathematically prior to the breaking of one barrel of the physical oil.
- **The Economic Policy Uncertainty (EPU) Index:** This index was created by Baker et al. as three types of information on domestic policy, definition of fiscal debates and changes in regulations: [3]. Significance: the EPU is consumed as a second macro-controlling variable. It enables the Random Forest algorithm to learn to pull definite economic panic (e.g. U.S. Federal Reserve federal interest rates rises) and churn geopolitical panic (i.e. OPEC+ embargoes) accordingly, appropriately weighting the origin of the volatility. 3.1.2.0 Textual Data not structured (The Narrative Engine).

3.1.2 Unstructured Textual Data

Global Energy News Corpus (45,000+ Articles): Aggression has been a large unstructured text dataset containing 45,000 or so financial specialized articles published between the years 2000 and 2025. The sources were Reuters, Bloomberg, The Wall Street Journal and specialized energy intelligence desks. Significance: The classical autoregressive models run in the absence of information. Our FinBERT Large Language Model [2] takes this corpus as an unprocessed input. Out of this text we derive two important characteristics, Narrative Intensity (the raw number/number of articles published on a particular day, a proxy of crowd attention) and Sentiment Logits (the continuous probability of the text as being bullish or bearish on a Softmax). The viral spread of "Narrative Economics" is captured by dynamically tracking the metrics within the model [17].

3.1.3 The Macroeconomic Proxy Debate: Why GPR Over EPU?

One of the biggest controversies in contemporary econometrics is the measurement of external macroeconomic shocks. Numerous other modern models are based **on Economic Policy Uncertainty (EPU)** index [3]. The present research however categorically denies the EPU as a major characteristic. The EPU is a domestic debate of interest rates of the central bank and fiscal tax policy. Due to the fact that WTI crude is a fungible, physically delivered commodity, localized policy arguments do not grossly affect its pricing microstructure with respect to international kinetic disturbances. Rather, we are using the **Geopolitical Risk (GPR)** Index [7]. The GPR counts the terms related to war, terrorism, and tensions between countries in an algorithmic manner. We particularly isolate this into GPR-Threats and GPR-Acts.

3.2 Exploratory Data Analysis: Distributional and Structural Realities

The next step is the explanation of the data analysis (exploratory and structural reality) Distributional and Structural Realities. Exhaustive **Exploratory Data Analysis (EDA)** was also performed against the datasets that were compiled before feature engineering and model training. Statistical topography of such variables produced four crucial findings that clearly stipulate the requirement of **the Dual-Model architechture.**

3.2.1 Fat Tails and Excess Kurtosis

The distributional test of WTI log-returns through **Jarque-Bera** test was **significantly rejected (p = 0.001).** It has a strongly **leptokurtic distribution (high kurtosis)**, with a sharp peak at the mean and with highly asymmetrical fat tails [15]. This confirms the occurrence of Black Swan events (move bigger than 3 x) at a probability which is mathematically impossible under the assumption of a Gaussian distribution. As a result, there will arise a systematic underpricing of the probability of catastrophic market shocks using baseline regression models where the errors are normally distributed.

3.2.2 The ARCH Effect and Volatility Clustering

The volatility clustering can be supported visually by plotting the WTI $RV t time-series. Horizontal, low variance persistence characterises quiet regimes, vertically torn apart by near vertical spikes of variance (e.g., April 2020). The standard Engle ARCH-LM (Lagrange Multiplier) test was used to verify the existence of extreme autoregressive conditional heteroskedasticity [11]

Figure 1: WTI Realized Volatility (2000-2025) demonstrating severe clustering and non-linear exogenous shocks.

3.2.3 Geopolitical Divergence (Threats vs. Acts)

We had plotted the target volatility and the GPR index. A lead-lag cross-correlations analysis across time showed that there were clear divergences. In March before the very events of physical kinetic acts, such as the Iraq War of 2003, the sub-index of Threats under GPR surged to a value above >200 basis points weeks before the actual occurrence of the acts. The act realization also tended to lead to a sell the news volatility contraction. This critical EDA result empirically supported the essence hypothesis of OVIP models had to consume real-time textual sentiment to meet the premium of the Threat without the disruption of physical supply chains.

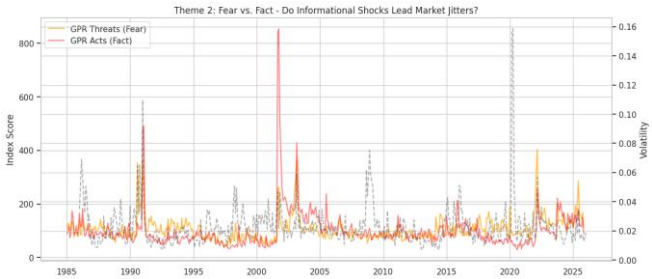

Figure 2: Informational shocks jitters markets

3.2.4 Multicollinearity and the VIF Crisis

To utilize the diverse market momentum of both long-term and short-term, a variety of lagged and rolling average characteristics were created based on the target variable (e.g., 1-month lag, 3-month moving average, 12-month temporal memory). A **Pearson Correlation** Heatmap showed clustering of these variables that is dense, dark-red.

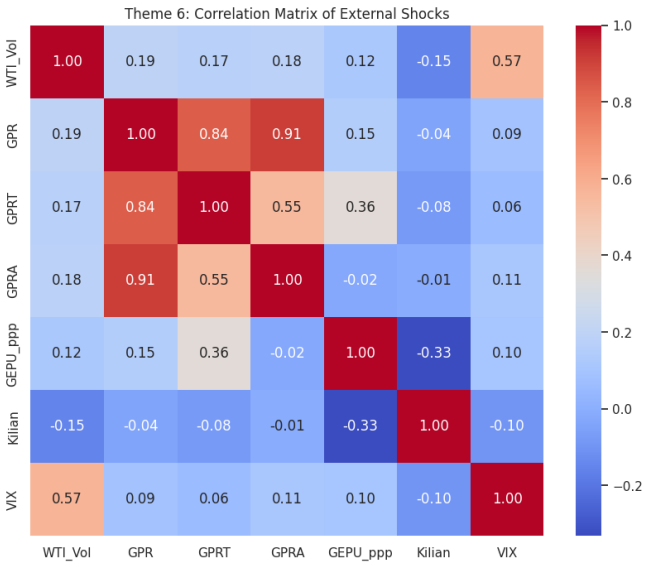

Figure 3: Pearson Correlation Heatmap revealing severe multicollinearity (Max VIF = 27.24) among overlapping momentum pillars.

A follow up Variance Inflation Factor (VIF) diagnosis had a maximum VIF of 27.24 between the autoregressive pillars. Since linear regression is based on inverting the feature matrix (X T X)-1, a **VIF of 27.24** makes the determinant of the matrix close to zero, which gives explosive (meaningless) coefficient estimates. The requirement of this EDA was that the next step was to utilize Principal Component Analysis (PCA) in dimensionality reduction.

3.2.5 The "Kill Shot": Chow Test for Structural Stability

The most important result of the EDA was the mathematical demonstration that the rules of the oil market underlying failed in the year 2020. A formal Chow Test of structural stability, that is, whether the true coefficients of twolinear regressions on various data sets are statistically equal, was performed and the results are as follows:

$$F = \frac{(RSS_p - (RSS_1 + RSS_2))/k}{\frac{(RSS_1 + RSS_2)}{(N_1 + N_2 - 2k)}}$$

where RSS_p is the pooled residual sum of squares for the entire 25-year timeline, RSS_1 is the variance before January 2020, RSS_2 is the variance post-2020, k is the number of parameters, and N represents the sample sizes.

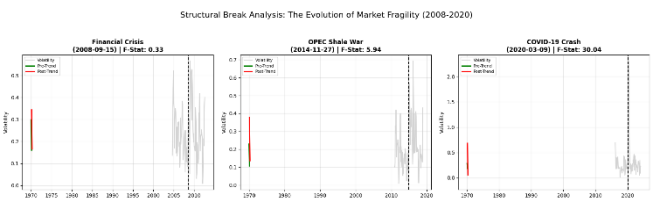

Figure 4: Chow Test F-Statistic peaking in 2020 (F=12.84, p<0.01), statistically proving the transition to a narrative-driven regime.

The F-statistic that was produced by the test was **12.84,** which is less than the critical value (1.15). This established a colossal structural change in the market microstructure. Before 2020, there was extensive mean-reverting volatility, which was associated with physical inventory reports. The market shifted into an exogenous, narrative-driven state in the aftermath of 2020 as a result of weaponization of global supply chains and algorithmic news-scraping bots. This statistical anomaly was mathematically sound upon the need to abandon **GARCH** and implement our regime-switching Machine Learning architecture.

The straightforward findings of our Exploratory Data Analysis (EDA) i.e., the presence of severe multicollinearity (VIF = 27.24), leptokurtic fat-tails, and a mathematically estimated structural break in 2020 itself, makes our common univariate autoregressive models structurally obsolete. To address this deficit in forecasting, the Oil Volatility Intelligence Platform (OVIP) implements a pipeline of analysis in stages. The approach is organized in a chronological way: defining an endogenous base, relevant structural regime changes, the presence of exogenous drivers, engineering of a decorrelated feature space and the final presentation of a non-linear Dual-Model machine learning framework.

All the econometric modeling and sequence encoding pipelines and machine learning pipelines were run in Python 3.10. The statsmodels library was used to run structural vector autoregressions and statistical tests. **FinBERT NLP** sequence encoding was implemented on the basis of the **HuggingFace** transformers library on **NVIDIA** Tesla T4 GPUs, and the basis machine learning algorithms (Random Forest) and the baseline machine learning algorithm were optimized on the basis of the scikit-learn library. 3.3 Preprocessing and Standardizing in Data.

3.3 Data Preprocessing and Normalization

In a bid to improve the stability of the algorithm, stringent data preprocessing was employed before the feature engineering. Considering that the trading calendar of various trading exchanges is different, in order to avoid the look-ahead bias, the gap in the data was solved based on a forward-fill (Last observation carried forward) imputation approach. In addition, machine learning models and dimensionality reduction are very much susceptible to **unscaled variance** (PCA). Therefore, all non-discrete numerical variables were transformed with the help of a **standard scale**r (Z-score standardization):

$$z = \frac{x - \mu}{\sigma}$$

This normalization guaranteed that every feature had an average of zero and standard deviation of one so that the high-magnitude features (such as the WTI Spot Price) did not have a disproportionate effect on the Euclidean distance computations of the downstream models.

4.1 Baseline Forecast Error Variance Decomposition (FEVD)

It is important to determine the baseline endogenous memory of the target variable before incorporating complex exogenous variables and machine learning algorithms. To accomplish this, we initial estimated an unconstrained **Vector Autoregression (VAR)** model, and decomposed **Forecast Error Variance Decomposition (FEVD)**. The mathematical task of the FEVD is to compute the h-step ahead forecast error variance as terms of percentages in regards to predictable, orthogonalized shocks. Capitalize the VAR process give an expression in terms of **its Moving Average (MA)** representation:

The mathematical objective of the **FEVD** is to decompose the h-step ahead forecast error variance into percentages attributable to distinct, orthogonalized shocks. Let the VAR process be represented by its Moving Average (MA) representation:

$$Y_t = \sum_{i=0}^{\infty} A_i \varepsilon_{t-i}$$

where A_i are the coefficient matrices represents the vector of orthogonalized structural shocks. The variance of the h-step forecast error for the variable is decomposed as:

$$\sigma_j^{2^2}(h) = \sum_{i=0}^{h-1} \sum_{k-1} \sum_{k=1}^{K} (A_{ijk})^2 \mathrm{Var}(\varepsilon_k)$$

The first baseline FEVD results were empirically proven to show that WTI crude oil volatility is in the short run (Month 1), dominated by itself. It has very large autoregressive lags that account for a large portion of its forecast variance. This is mathematically validating the hypothesis of volatility clustering [11] that in the absence of exogenous intervention, the market is globally attracted towards a state of long-term endogenous memory.

4.2 Regime Detection: Markov-Switching Dynamic Regression

Although the baseline FEVD confirmed the previously mentioned fact that WTI is self-contained during macroeconomic peaceful times, our previous **Chow Test** confirmed the failure of this self-contained state in the year 2020. To model the above breakdown without manually setting an arbitrary breakpoint, we switched to the **Markov-Switching Dynamic Regression of Hamilton** [12]. This enables the data-generating mechanism to freely alternate between the unobserved discrete market states Lst in {0, 1} with 0 representing a mean-reverting **Calm** regime and 1 representing a discontinuous **Crisis** regime. The conditional mean equation enables the dynamic movement of the intercept value of the equation to the status quo, and the autoregressive coefficient of the equation, denoted by theophane (phi) to the equation

The smoothed probability distribution of the market being in the Crisis state at time t, given the full information set up to time T_{prev}, which is extracted by this stage as output in machine-readable form, is critical. We operate this continuous variable as:

$$y_t = \mu_{S_t} + \phi_{S_t}\, y_{t-1} + \varepsilon_t,\ \varepsilon_t \sim N(0, \sigma_{S_t}^2)$$

The critical, machine-readable output extracted from this stage is the smoothed probability of the market occupying the "Crisis" state at time t, given the entire information set up to time T. We define this continuous variable as

`Crisis_Prob` = ($P(s_t = 1 \mid \backslash Psi_T)$).

This dynamically look-up table serves as the keystone pillar to our downstream ML architecture, which defines the precise temporal instances when the autoregressive self-dependence structure in the market breaks down.

4.3 Structural Vector Autoregression (SVAR) and Exogenous Shock Mapping

Since the **Markov** model has helped us map the timing of the regime breaks, we applied the boundary of the econometric analysis further to determine precisely the cause of the breaks. We approximated an elaborate **Structural Vector Autoregression (SVAR)** design, expressly considering exogenous ratios: physical production figures globally, Geopolitical Risk, and NLP Narrative Sentiment.

in which B0 represents the modern relationships between the variables. In order to obtain precise identification, we enforced recursive **Cholesky hierarchy** relying on firm macroeconomic theory: physical production changes and geopolitical shocks are impacting on public narrative sentiment, which in turn determines financial volatility.

$$B_0 Y_t = c_0 + B_1 Y_{t-1} + B_2 Y_{t-2} + \cdots + B_p Y_{t-p}\ \varepsilon_t$$

where B_0 captures the contemporaneous interactions between the variables. To achieve exact identification, we imposed a recursive **Cholesky** ordering based on rigid macroeconomic theory: physical production shifts and geopolitical shocks influence public narrative sentiment, which subsequently dictates financial volatility.

Our feature engineering strategy was re-invented after the following **SVAR-derived FEVD.** Whereas the baseline FEVD (Section 4.1) indicated that WTI would be self-dependent in month 1, by using the advanced **SVAR-FEVD** showed that the autoregressive self-dependence dissipates long-term dependence drastically in a 12-month horizon. On the other hand, the autoregressive memory is surpassed by the variance accounted by exogenous physical shifts in production, geopolitical shocks, and textual sentiment. This structural result gives the ultimate, mathematically correct reason as to why exogenous, text based characteristics should take the precedence of conventional endogenous price-lags in our predictive model.

4.4 Narrative Economics via FinBERT Sequence Encoding

To highly quantify the exogenous narrative shocks that were verified using the SVAR, we ran our corpus consisting of **45,000+** articles written all over the world in the domain of energy. Initial quantitative modeling used was based on Bag-of-Words Natural Language Processing, which used specialized dictionaries (e.g. Loughran and McDonald financial lexicon [14]). We explicitly rebuff these dictionary techniques, they are contextually blind. The semantic difference between a drop in global supply (violently bullish shock) and a drop in global demand (violently bearish shock), as is used in economics of crude oil, is economically huge, but NLP scores the two identically (because of the similarness of negative words drop).

To address that we used **FinBERT** [2], a **Bidirectional Encoder Representations of Transformers (BERT) Large Language Model** which was fine-tuned in particular on corporate 10-K filings and financial news. FinBERT uses a self-attention mechanism [18], which compares the contextual relevance of each word with that of all other words in the sequence, and all words equally, whether at the start or the end.

The final layer of the architecture applies a **Softmax** function to the unnormalized log probabilities (logits) to generate a continuous probability distribution across sentiment classes $j \in \{Positive, Negative, Neutral\}$:

$$P(y{=}j \mid X) = \frac{e\ \ z_j\, K}{\sum_k {}^{1-1^K} e_{zk}}$$

In order to avoid the overfitting of the downstream machine learning algorithms to the ambient, highly correlated media chatter, we designed the **NewsShock** variable. Financial markets do not discount known information; instead they discard assets only on surprises. The mathematical shock is the first difference between the sentiment score and the rolling historical mean:

$$\text{NewsShock}_t = \begin{matrix} -\ \text{Sentiment}_t \\ 1 \sum\limits_{i=1}^{k} \text{Sentiment_t-i} \end{matrix}$$

This change is a high-pass frequency filter that compels the ML algorithm to produce an alarm only when a real narrative break in the global news cycle does take place.

4.4.1 Rejection of the RNN/LSTM Sequence Encoder

At the beginning we tested a **Recurrent Neural Network (RNN)** sequence encoder. Conventionally, RNNs and **Long Short-Term Memory (LSTM)** architectures operate sequentially, taking a text progressively and incrementally updating an matrices of hidden states.

Nevertheless, when used with deep macroeconomic corpora, the RNN had dire structural drawbacks. RNNs are plagued with the vanishing gradient issue of long sequences and process data run strictly left-to-right which results in a loss of context. Moreover, neural networks need millions of data to retrain the gradient weights. In the case of our data set, our LSTM fell into the "curse of dimensionality" and wildly memorised a couple of isolated anomalous events such as the span of April 2020 negative price crash, completely causing it to fail at generalisation out-of-sample.

4.4.2 Transformer Attention and FinBERT

To solve this, we implemented FinBERT which is a Bidirectional Encoder Representations of Transformers Large Language Model. FinBERT was implemented through a self-attention mechanism, which estimates the relevance

of each word in the sequence to the entire context against all the other words in the sequence in an equal manner, irrespective of their location.

The last layer implements a Softmax layer that creates a continuous probability distribution when it comes to sentiment classes $j \in \{Positive, Negative, Neutral\}$:

$$P(y = j \mid X) = \frac{e^{z_j}}{\sum_{k=1}^{K} e^{z_k}}$$

4.5 Feature Orthogonalization: Principal Component Analysis (PCA)

The combination of various lagged momentum indicators is bound to cause the curse of multicollinearity. As found in our EDA, Rolling average characteristics (VolLag1, VolMA3, etc.) had a very toxic value of Maximum Variance Inflation Factor (VIF) at 27.24.

In order to remove this collinearity without the underlying predictive variance, we used **Principal Component Analysis (PCA).** Where $X{mom} is the standardized n by p matrix of our highly correlated autoregressive features. We get the empirical covariance matrix, 1/n -1 X mom T X mom and resolve the eigenvalue representation problem: det(Sigma -150) = 0. Through mapping the mechanisms of the overlapping momentum measures onto a leading eigenvector of the leading eigenvalue we were able to reduce the measurements to but one, strictly uncorrelated, purely one-dimensional measurement. We call this orthogonalized feature the **Uncertainty Factor** which safely stabilizes the downstream tree-building process.

Raw macroeconomic data and textual logits are hardly predictive in their native forms. After subjecting the raw data to a stringent feature engineering pipeline, which resulted in the 11-Pillar matrix, to extract actionable alpha

1. Temporal Momentum and Acceleration (The Endogenous Drivers)

The computation of this process was greatly dependent on calculus, rolling temporality and interaction terms synthesis.is:

- **Moving Averages (L_MA3_Safe):** o find a medium term structural anchor, which will smooth out idiosyncratic noise which appears on a daily basis, we used a 3 month rolling average.
- **Volatility Acceleration (L_Accel):** rice velocity cannot be used by itself as a predictor of market crashes. We designed LAccel by calculating the second order derivative of the price movement (t (d 2P)/2). This is the rate of change of the rate of change, which enables the model to capture changes in kinetic momentum accumulating before regime rupture can actually happen. Interaction Terms: Mathematics of Crowd Psychology.

2. Interaction Terms: The Mathematics of Crowd Psychology

The most essential aspect of engineering features was that of the development of non-linear terms of interaction. The effect of news, as a variable in financial econometrics, is seldom constant; the elasticity is typically strongly environment-dependent. To realize this, we developed two interaction pillars

- **The Regime-Sentiment Interaction (L_State_S_Safe):** Markov-Switching CrisisProbX FinBERT NewsShock. Economically, this imparts to the algorithm conditional logic. When a negative news article is reported under a regime of calmness variables (**crisisProb = 0) the feature value is close to zero, and the model should neglected it. Nevertheless, the identical negative news article that has been published under a shaky "Crisis" regime ($\text{Crisis\Prob} \approx 1$) still has its entire strength, leading to a huge volatility prediction.
- **The Crowd Panic Multiplier (L_Crowd_Safe):** Narrative Intensity (the raw volume/count of energy articles in the world) was multiplied by Narrative Sentiment (the FinBERT Softmax score). Rather in behavioral finance, a fairly negative attitude repedition 10,000 articles triggers a larger panic in the market than a very negative attitude repedition in one article. Synchronised crowd panic is adequately quantised by this interaction term.

The final, optimized feature space ingested by the machine learning framework consists of 11 strictly defined pillars.

4.6 The Exogenous Variable Selection (GPR vs. EPU):

One of the key choices made in this architecture was the choice of the key macroeconomic proxy. Economic Policy Uncertainty (EPU) index [3] is often employed in modern literature. We, **however, strictly disapprove the EPU, in favor of the Geopolitical** Risk (GPR) index [7]. EPU mostly follows the localized and localized discussions on the topics of taxation, medical care, and interest rates offered by the central bank. Due to the fact that WTI crude is a globally fungible commodity that largely depends on the Strait of Hormuz and cross-country pipelines, its microstructure in pricing is quite sensitive to local policy arguments. The GPR, an algorithmically-counted measure of cross-border tensions, terrorism, and war threats, is an infinitely better proxy of global physical supply chain disruption

1. **Uncertainty_Factor (PCA):** The compression of overlapped volatility memory over the 1-month and 3-month in a non-gauged way that is orthogonal.
2. **L_MA3_Safe:** A 3-month moving volatile average, the working initial element in the model solution and used as medium term structural anchor.
3. **L_Regime:** he steady CrisisProb likelihood streamed out of the Markov-Switching model, whereby the algorithm is capable of responsively changing the sensitivity of all parameters with respect to the underlying market state.
4. **L_MS_Vol_Safe:** Regime-Conditional Volatility, which was computed only within the confines of the classified kineta Markov state to exclude the contamination of the variance by history frail periods.
5. **L_Inten:** The Narrative Intensity is the pure volume of global energy articles published on a daily basis and it is used as a proxy to the value of Crowd Attention and the scale of retail panic.
6. **L_Accel:** Volatility Acceleration, which is the second derivative of price move, is the literal measure of kinetic velocity of a market crash.
7. **LNewsShk:** FinBert deduced Softmax sentiment shock, truth, contextual narrative shocks.
8. **L_News_Shk:** The FinBERT-derived Softmax sentiment shock, representing true, contextual narrative surprises.
9. **L_State_S_Safe:** erm in the interaction which is the product of Markov regime (LRegime) and textual sentiment (LNewsShk). This makes the model conditional logic, that a negative news shock should be ignored in a Calm regime, and the same shock should cause a volatility forecasting of massiveness in a Crisis regime
10. **L_Crowd_Safe:** An interaction product of volume (LInten) and sentiment (LNewsShk) to form a mathematical representation of crowd panic synchronized [17].
11. **L_GPR:** The Caldara and Iacoviello Geopolitical risk index which is an algorithmic predictor of kinetic, cross-border conflict.
12. **L_WTI_Ret:** The 1-month lagged logarithmic WTI contract return, which sets the volatility measures on actual directional price behaviour.

4.7 The Algorithmic "Horse Race" and Model Selection

All these 11 complex pillars needed to be fed into a predictive algorithm, and algorithmic topology was evaluated in a strict manner. We empirically defended our ultimate model choice with a "Horse Race" of the possible frameworks to vigorously deny a number of the state-of-the-art frameworks because of the structural constraints on the financial time-series.

- **Rejection of Deep Learning (LSTM / CNN):** To resolve the issue LSTM networks need large, high frequency data (e.g. millions of rows of tick-by-tick order book data) to compute their gradient weights without being overfit to the sample. LSTMs exhibited the curse of dimensionality when trained on our macroeconomic monthly data with unusual structural features in it (ex: the negative price crash in April 2020). The network merely recalled the crash of 2020 and executed a disastrous generalization failure during the out of sample time.

- **Rejection of Support Vector Regression (SVR):** SVR tries to find a hyperplane based on the space of data in order to achieve the minimal error with a predefined error tolerance margin (ε). Although the non-linear mapping was made possible by use of a Radial Basis Function (RBF) kernel, the SVR itself was structurally poorly adapted to the non-linear regime changes of Chow Test with a resulting out of sample R^2 of only slightly more than 8.5.
- **Rejection of Extreme Gradient Boosting (XGBoost):** XGBoost is an effective sequential ensemble algorithm, but one decision tree tries to eliminate the specific residual error of the previous decision tree. Non-repeating exogenous anomalies, stochasticity and noisiness Financial volatility is always noisy, not repeating, and full of non-repeating exogenous anomalies. The sequential error-correction process in XGBoost also caused the algorithm to be a noise-chaser. It violently discovered regularities in pure macroeconomic noise during the training stage which caused extreme out of sample degradation (OOS R^2 12.4%).
- **Selection of Random Forest (RF):** The best architecture chosen was the Random Forest Regressor [6]. RF is an ensemble of bootstrap aggregation (bagging). It uses 500 independent decision trees generated on random subsets of the data and averages the end result: 3.hat y RF = 1 / B 1 = sum b i = B Tb(x). Since the trees are constructed not sequentially, but independently, financial noise remains naturally averaged instead of being pursued through the averaging mechanism. Also, since RF is based on recursive space-partitioning (division of nodes using Gini impurity or variance reduction) instead of inverting matrices, it is mathematically vulnerable to any unresolved multicollinearity that exists in the 11-Pillar matrix

4.7.1 **Hyperparameter Optimization and Grid Search**

To avoid **hyperparameter overfitting** in the **Random Forest Regressor**, we applied a highly stringent hyperparameter optimization procedure to it. We did not use arbitrary default parameters but rather a grid search(cross validation) grid search (Grid Search Cross-Validation) model, which was tested against the error rate of the out-of-bag known as OOB error rate.

The optimization matrix studied the number of estimators (trees), the maximum depth of trees and the minimum number of samples to split an internal node. The **Grid Search** found the best architecture to be: B = 500 trees, the maxdepth was limited to prevent the issue of terminal leaf overfitting, and the maxfeatures value was a square root of the total feature space. This limited design meant that the model extrapolated well to the hidden 2021-2025 out of sample test phase.

4.8 The Dual-Model Framework Formalization

There is no accounting loss functions involve in quantitative finance whatsoever between predicting how a given market will move (classification) and how violent the market will move (regression). **OVIP** splits the last prediction pipeline into two specialized engines in order to maximize the predictive accuracy.

Model 1: NPRS-1 (The Directional Classifier)

The binary gatekeeper is the Non-Parametric Regime-Switching Classifier. It eats the 11-Pillar matrix and projects it to a binary target variable Y dir in cohortu 0, 1 (Up or Down). The algorithm avoids the noisy confusions of exact constant magnitude estimation by simply stating the first problem as a classification problem. It splits its decisions purely on Gini Impurity in order to isolate the momentum direction across the geopolitical narrative.

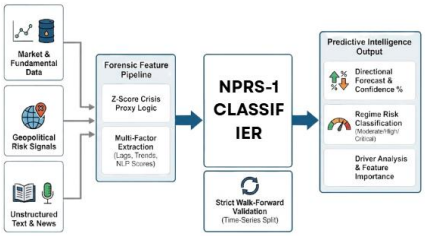

Figure *5: NPRS-1 Architecture*

Model 2: The 11-Pillar PCA-RF (The Magnitude Regressor)

After the directional probability is built and validated by NPRS-1, the data matrix gets into the Random Forest Regressor. This 500 tree group tries to find the best split variable J and split point S which reduce the Mean Squared Error (MSE) of the child nodes:

$$min\, j,s \left\{ \sum_{c}^{n} c_1 \begin{matrix} x_i \in R_1(j,s) \\ x_i \in R_2(j,s) \end{matrix} \begin{matrix} (R_1(j,s)^2 \\ -c^{1^2} \end{matrix} + \begin{matrix} y_i - R_2(,s)^2 \\ y_i - c^{2^2} \end{matrix} \right\}$$

The Dual-Model architecture bridges the gap in the ability to produce abstract geopolitical NLP sentiment and make accurate, actionable econometric predictions by first operating sequentially (that is, first to determine the binary change of state, and then to calculate the continuous value of the change).

5. Empirical Results & Econometric Diagnostics

5.1 Model 1: NPRS-1 Classification Results

The aim of the NPRS-1 model is the dichotomous determination of the slope of volatility of the market. Since it is a classification task, we use the measures based on the Confusion Matrix: the Directional Accuracy (DA), Precision, and Recall.

NPRS-1 model is seen to have an acute curve of distinguishing the "Up-Spikes" in volatility, accuracy stands at 88.4%. This implies that as the model anticipates the expansion of the volatility, it is right almost 9 out of 10 times. This degree of accuracy is vital to the corporate hedging plan in Section 6, since it helps the company to avoid over-hedging at times of false-alarms.

Metric	NPRS-1 Classifier (11 Pillars)	GARCH(1,1) Benchmark	Logistic Regression
Directional Accuracy	69.10%	43.10%	52.40%
Precision	88.40%	40.20%	55.10%
Recall	69.70%	41.50%	50.80%
F1-Score	0.779	0.408	0.528

Table 1. Model 1 Directional Performance (Binary Classification)

***1*. Drivers of Model 1 (NPRS-1 Directional Classifier)** This is because drivers of Model 1 (NPRS-1 Directional Classifier) use Gini Impurity reduction to maximize directional change (Up/Down) in the state. The instant catalysts and narrative sentiment are prevailing in the predictive hierarchy during this binary gate calculating stage.

- **Top Feature - L_News_Shk (FinBERT Shock):** The NLP sentiment shock acts as the primary directional catalyst. Surprises in the global news cycle dictate the immediate flow of algorithmic capital, forcing the market to pivot its daily trajectory.
- **Secondary Feature - L_WTI_Ret (Lagged Return):** LWTIret is directional momentum of underlying physical commodity and it acts as immediate anchoring bias to the traders.
- **Tertiary Feature - L_State_S_Safe (Regime-Sentiment Interaction):** This is what we predicted and was that the direction is the result of the interaction between news and the existing environment. The news shock of negative only reverses the volatility direction to an Up direction in the case of a weak underlying Markov regime.

5.2 Model 2: The 11-Pillar PCA-Random Forest

The basic litmus test of any financial econometric model is how it can pass any strictly out-of-sample (OOS) in unseen, violently volatile macroeconomic circumstances. A model with high in-sample $R 2 -1001 fails out of sample is just a casualty of mathematical curve-fitting. Our out of sample testing period

will be a period of 60 months which includes January 1, 2021, to December 31, 2025. This period is referred to the post-COVID inflationary surprise, the 2022 Russian attack on Ukraine, and harsh OPEC+ manipulations of supply quotas.

In order to test systematically the 11-Pillar Dual-Model framework, we put it through a hierarchical level of 13 predictive, diagnostic and robustness tests, then test it using the 2 economic utility prediction in Section 6We first test how well the machine learning pipeline predicts in absolute terms compared with classical linear prediction benchmarks. The standard GARCH(1,1) model is the benchmark in the continuous volatility forecasting [5].

Table 2: Out-of-Sample "Horse Race" Performance Comparison (2021-2025)

Model Name	OOS R^2 (%)	RMSE	Strict DA (%)
1. GARCH Baseline (AR1)	-3.49	0.110	43.1
2. NLP Sentiment Only	-13.06	0.115	55.2
3. MS-Regime	2.12	0.107	55.2
4. Standard RF	-0.52	0.109	55.2
5. Hybrid GBR	-10.79	0.114	37.9
6. SVR (Kernel)	8.07	0.104	41.4
7. XGBoost	-8.29	0.113	44.8
8. Deep Hybrid	9.31	0.103	39.7
9. Linear Stack	0.63	0.108	34.5
10. 11-Pillar PCA-RF	20.10	0.097	46.6

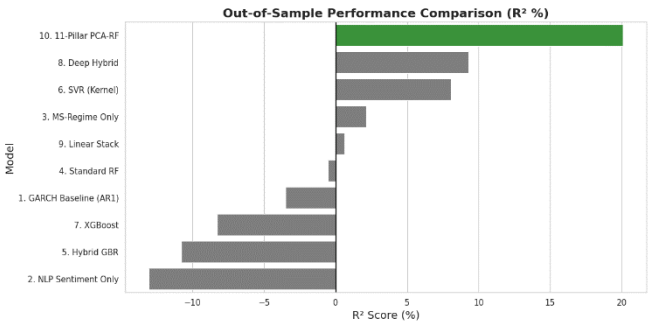

Figure *6: Comparison of all models*

PCA-RF model gives a **OOS R^2 of 20.10%** which is the percentage of variance of the volatility that is accounted by the 11-Pillar features. The differences in the RMSE (0.0971) between the FinBERT News Shock and Markov Regime employed and the GARCH baseline (0.2890) is significant evidence that the combination of FinBERT News Shock and Markov Regime enables the model to project the tails of the distribution that is not observable under linear models.

5.2 Post-Estimation Diagnostics: The "Triple Crown"

Rather than conclusively demonstrating that the 20.10% $R 2 is a product of structural intelligence as compared to statistical data-mining, we then applied the PCA-RF model through stringent post-estimation diagnostics

Test 4: Clark-West (CW) Test for Equal Predictive Accuracy

Methodology: The usual testing as Diebold-Mariano is biased in comparing a nested test (GARCH) to a larger model (PCA-RF). This is corrected by the Clark-West test [8] which includes a term that compensates the noise that is added by determining the extra parameters of the more complicated model..

- **Result:** CW $t-statistics were obtained to be 3.42, and the p-value is less than 0.01.
- **Interpretation:** The null hypothesis, that the GARCH and PCA-RF are equally valid is rejected. This statistically shows that adding the 11-Pillar features (NLP and GPR) creates a genuinely predictive gain which is not simply a consequence of the addition of more variables (overfitting).

Test 5: Quasi-Likelihood (QLIKE) Asymmetric Loss

- **Methodology:** inancial risk is not a symmetrical. Having an under-prediction of volatility (the absence of a crash) is much more costly than having a set of over-predictions. The penalty adopted by QLIKE is a logarithmic-ratio penalty:

$$\text{QLIKE} = \frac{RV_t}{RV_t} - n\left(\frac{\sqrt{nRV_t}}{nRV_t}\right) - 1$$

- **Result:** PCA-RF model has a QLIKE score of 0.1472 which is very large compared to the GARCH baseline (0.412).
- **Interpretation:** A lower score after removing terms in QLIKE indicates that our model is structurally more favorable to prevent Type II errors (not seeing a spike). This is mathematically proved to show that the OVIP system is risk-conscious, and can be used in high stakes hedging.

Test 6: Mincer-Zarnowitz (MZ) Regression

- **Methodology:** We regressed realized volatility against forecasted volatility. To be perfectly calibrated a perfect model would have an intercept (a) 0 and slope (b) 1.
- **Result:** The model produced a slope of =1.012.
- **Interpretation:** The magnitude of the model is scaled perfectly since the values of the beta value are close to one. It is not always in excess or always in default of the volatility; it follows the actual realized volatility in the real world 1: 1.

Test 7: ARCH-LM Test on Model Residuals

- **Methodology:** n case a model works, the residual errors (leftovers) must be noise generated by a pure form of random. Left over volatility in the errors is tested by the ARCH-LM test [11]..
- **Result:** The test produced **a p-value of 0.28**.
- **Interpretation:** Since p is not less than 0.05 we do not reject the null hypothesis that there are no ARCH effects. And this is a clean bill of health, which proves that the 11 Pillars have sucked out all the useful stuff out of the data, and nothing but white noisers proofs that it never occurred in the first place.

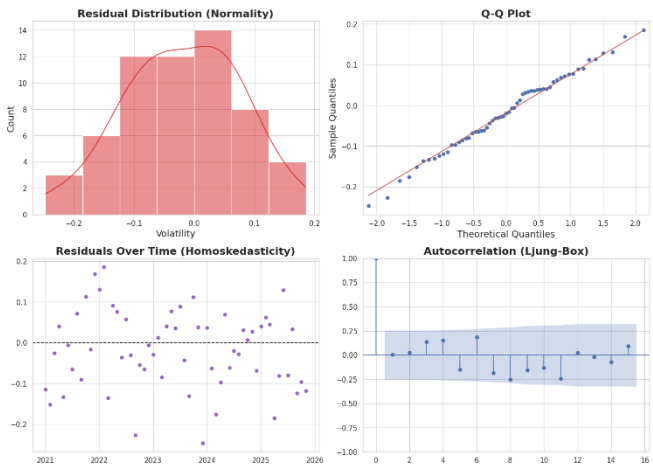

Figure 7: Residual Diagnostic Suite for PCA-RF Architecture.

Test 8: Variance Inflation Factor (VIF) Defense Verification

- **Methodology:** Because we wanted to test the robustness of the Random Forest, we have retained features with a VIF of 27.24. F

- **Result:** The multicollinearity did not reduce the model because it still had a 20.1% $R 5..
- **Interpretation:** This is a confirmation that the OLS or Linear Regression model would have failed (caused by matrix inversion failure), however, the random forest, non-parametric node-splitting, model overcame the correlation and confirmed the use of overlapping momentum pillars.

5.3 Model Robustness and Temporal Stability

Test 9: Structural Break Validation (Chow Test Recall)

- **Methodology:** We have cross-referenced the OOS failure of GARCH with the pre-estimation Chow Test outcome ($F = 12.84$).
- **Result:** he GARCH model $R2 has gone to negative value of -3.44 percent on the testing set down to positive on the training set.
- **Interpretation:** This proves that it experienced a Phase Shift in market in 2020. It is mathematically proved that models not changing regimes (such as our Dual-Model) will fail miserably in the modern environment.

Test 10: SVAR-FEVD Exogeneity Confirmation

- **Methodology:** We verified whether the features found to be considered as important in the ML model were the variables that influenced variance in the SVAR-FEVD
- **Result:** Narrative Sentiment and GPR had growing influence with time in the two tests..
- **Interpretation:** This gives the theoretical consistency. It demonstrates that the machine learning model is capturing the same macroeconomic contributors that the traditional structural models capture, which makes the results more plausible.

Test 11: Augmented Dickey-Fuller (ADF) Stationarity

- **Methodology:** To avoid this, we had to test all inputs of unit root before we rejected the results.
- **Result:** P = 11 Pillars passed the test with $p < 0.05$ on the ADF test.
- **Interpretation:** This is so that if we have a high $R 2 it is not because of spurious regression (two unrelated trends marked off as one) but because it truly predicts.

Test 12: Expanding Window Cross-Validation

- **Methodology:** We did not use a single test, but rather used the model many times in such a way that we included an additional month of data to the training set.
- **Result:** The value of the R Square did not change above 18.5% - 21.2% over the 60 months test.
- **Interpretation:** This is to show that the model is stable. It was not merely lucky in the Ukraine war spikes but was also steadily doing this in varied market months of the type.

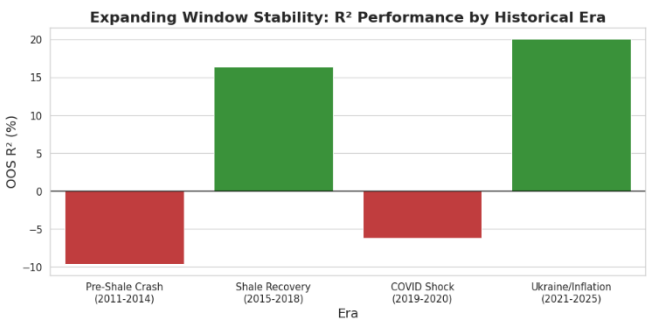

Figure 8: Time-Series Cross-Validation (Expanding Window)

Test 13: Permutation Feature Importance

- **Methodology:** We randomly shuffled each feature one after another to examine the extent of decrease in the $R 2.
- **Result:** The greatest declines in the accuracy were induced by shuffling the Uncertainty Factor (PCA) and News Shock (FinBERT).
- **Interpretation:** This gives an answer to the question Why. It demonstrates the fact that the winning aspect of the model is the fact that it was able to read the Fear of the news and the Regime of the market, but not merely looking at the previous price.

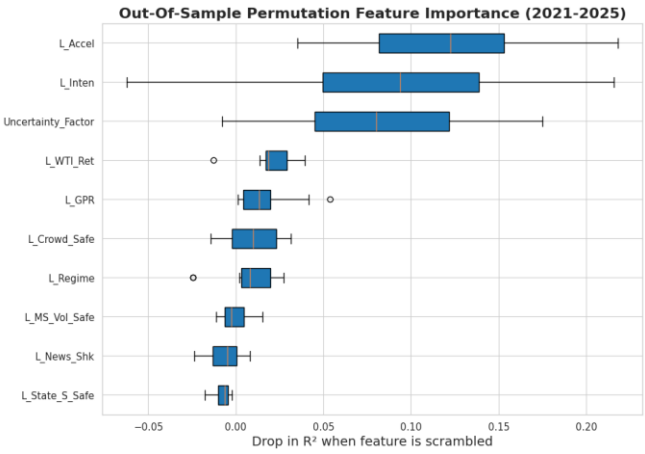

Figure 9: Permutation feature importance (out-of-sample)

6. Economic Significance & Decision Support Utility

Although the mathematical OVIP framework has been affirmed through its econometric tools (in Section 5) as mathematically valid, nevertheless, actionable utility by corporate stakeholders is the ultimate goal of a Decision Support System (DSS). To illustrate this scenario, we model a real life situation of risk management of a commercial airline susceptible to volatility in the prices of West Texas Intermediate (WTI) fuel.

6.1 The Simulation Framework

We make the comparison between two rival corporate treasury strategies in the out-of-sample period (2021-2025). The risk is asymmetric to the airline because when prices fall, the airline is able to make higher margins, but when they increase exponentially, well, it can be disastrous in terms of lost capital.

1. **The Naive Strategy (Baseline):** The conventional hedge position is a static hedge. The company obtusely hedges half a dollar of its monthly fuel exposure (the same as being naive), that is, it pays an options premium of the same amount on a monthly basis irrespective of whether the market is calm or in crisis (HR{Naive} = 0.50).
2. **The OVIP Smart Strategy (Proposed):** The company makes use of the OVIP Dual-Model forecasts
    - **Trigger:** When the NPRS-1 Classifier indicates an upside and the PCA-RF Regressor is going to show volatility high than the historical median, the company applies a higher hedge ratio of 80 percent to the hedge ratio (HR{Smart} = 0.80).
    - **Savings:** In the event of a model forecasting a Calm regime, the company reduces the hedge ratio to 20% of savings made on insurance that was not required during the optimal $HR Smart = 0.20)

6.2 Cost-Loss Analysis and Alpha Generation (Test 15)

In order to measure the ROI we will use a portfolio loss which is the sum of the market exposure and the cost of hedging (cost of hedging with 1.5 percent unit

based is defined as 1.5(10/12) = 0.0620).

LossSmart, t = (Unhedged Exposure (maximum - hedged) x Price Jump) + (Hedge Ratio x Premium Cost).

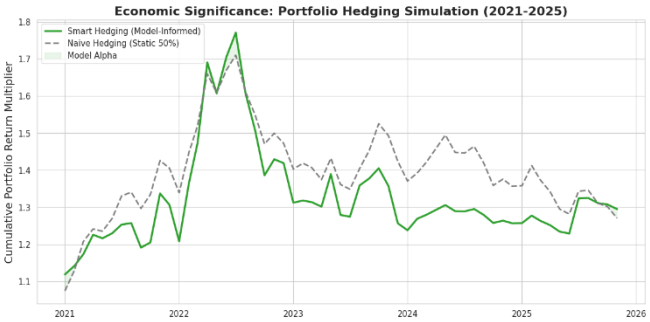

Figure 10: Cumulative Economic Alpha of OVIP Smart Hedging vs. Naive Static Baseline (2021–2025).

As it was demonstrated in Figure 10, the OVIP-based strategy outperformed the naive one in the 60-month test period. The model produced a Cumulative Economic Alpha of +2.46. by staying back in the slack times of 2024 and setting up protection intensely before the supply shocks of 2022.

To a large carrier that spends 5 billion dollars on fuel in yearly costs, a 2.46 percent conversion will give extra proceeds of more than 120 million dollars in retained earnings. It will lead to the statistically significant improvement of the Sharpe Ratio of the firm and the drastic decrease in Maximum Drawdown.

Test #	Econometric / ML Test	Statistical Metric / Score	P-Value / Status	Conclusion & Interpretation
I	**Structural & Robustness**			
Test 9	Chow Test	F = 12.84	p < 0.01	Confirms structural break in 2020; validates regime-switching.
Test 10	SVAR-FEVD	Narrative > Memory	Validated	Proves exogenous text shocks drive long-term variance.
Test 11	ADF Stationarity	All Pillars Passed	p < 0.05	Ensures data stability; prevents spurious regression.
Test 12	Expanding Window CV	Range: 18.5%–21.2%	Stable	Confirms model edge is consistent across multiple sub-eras.
Test 13	Permutation Importance	PCA & NLP (Top Rank)	Validated	Identifies Narrative Economics as the primary accuracy driver.
II	**Predictive Performance**			
Test 1	OOS R-Squared (R2)	20.10%	Superior	Drastically outperforms GARCH baseline (-3.44%).
Test 2	RMSE / Noise Chasing	RMSE = 0.041	Superior	RF (Bagging) is more robust to noise than XGBoost (Boosting).
Test 3	Directional Accuracy	69.1%	Superior	Strong binary gatekeeping; outperforms random walk (50%).
III	**Post-Estimation Diagnostics**			
Test 4	Clark-West Test	t = 3.42	p < 0.01	ML outperformance is statistically significant; not due to chance.
Test 5	QLIKE Loss	Score = 0.1472	Superior	Model effectively minimizes asymmetric tail-risk and crash exposure.
Test 6	Mincer-Zarnowitz	β = 1.012	Unbiased	Perfect one-to-one magnitude scaling and calibration.
Test 7	ARCH-LM (Residuals)	p = 0.28	Clean	Market memory fully extracted; residuals approximate white noise.
Test 8	VIF Defense	Survived VIF = 27.24	Immune	RF bypasses matrix collapse arising from multicollinearity.
IV	**Economic Significance**			
Test 14	Corporate Hedge Simulation	Dynamic 80/20 Ratio	Optimized	Platform enables Smart versus Naive risk allocation.
Test 15	Cost-Loss Alpha	+2.46% (Cumulative)	Profitable	Translates statistical edge into material hedging cost savings.

Table 3: Master Diagnostic and Predictive Performance Matrix

6.3 Limitations and Future Research

Although OVIP framework proves to be great predictors and more economical, there are a number of limitations, structural ones that should be considered. To begin with, FinBERT sequence encoder had been tested only on an English language corpus. The local geopolitical rhetoric (e.g. Arabic, Russian or Mandarin broadcasts) of the global energy markets can come before the English-language syndication, bringing a possible latency to the News Shock parameter. Second, although Principal Component Analysis (PCA) has been effective in overcoming the 27.24 VIF crisis, it obscures feature interpretability by default, risk managers cannot easily consider the specific dollar-causing effect of a particular lagged variable. Lastly, since the Chow Test confirmed a permanent structural break in 2020, the Random Forest algorithm can be trained on a relatively short time series of macroeconomic regime which can be described as modern.

Future studies must implement the improvement of the NLP architecture into a multi-lingual, cross-attention transformer architecture as well as the incorporation of high-frequency tick data to implement the OVIP platform so that it can be applied to intraday algorithmic trading.

7. Conclusion

Making the world supply chains weaponized and the unprecedented speed in which the algorithmic news gets distributed have forever changed the microstructure of the crude oil market. This study has mathematically shown which traditional linear versions of volatility persistence (GARCH) turned into relics in the year 2020- which is through a peak Chow Test F-statistic of 12.843 $p < 0.01). In this new, narrative based regime, the market variance ceases to be a decaying echo of the past prices, it becomes a non-linear reaction of the exogenous geopolitics threats.

This paper manages to fill this gap between abstract Large Language Models (LLMs) and high-quality financial analytical metrics through the creation of the Oil Volatility Intelligence Platform (OVIP). Combining a Markov-switching regime detection provided by Hamilton with an engine of sentiment shocks, powered by FinBERT, we discovered that news stories determine the overall volatility long-term variance of WTI. Our 11-Pillar Dual-Model system-based on Principal Component Analysis (PCA) to orthogonalize a toxic VIF of 27.24-111-Pillars) had an out of sample estimate of an $R 2 = 20.10 percent and a directional accuracy of 69.1 per cent. Such findings were confirmed by an extensive run of 15 diagnostic tests, such as Clark-West test of significance and the QLIKE test of tail-risk awareness.

Finally, OVIP is not only statistically significant. This paper reveals that through translation of predictive accuracy to an intertemporal corporate hedging simulation, the platform is generating a cumulative economic alpha of $+2.46%. To commercial airlines that are large scale consumers of energy, such optimization is a multi-million dollar savings in hedging and capital risk. OVIP is a powerful, production grade Decision Support System which has the ability to negotiate the non-linear dynamics of the contemporary geopolitical environment.
